NOAA TECHNICAL REPORTS

National Ocean Service Series

The National Ocean Service (NOS) provides charts and related information for the safe navigation of marine and air commerce. The service also furnishes other Earth science data--from geodetic, hydrographic, oceanographic, gravimetric, and astronomic surveys, observations investigations, and measurements--to protect life and property and to meet the needs of engineering, scientific, defense, commercial, and industrial interests.

Because many of these reports deal with new practices and techniques, the views expressed are those of the authors and do not necessarily represent final service policy. NOS series NOAA Technical Reports is a continuation of, and retains the consecutive numbering sequence of, the former series, Environmental Science Services Administration (ESSA) Technical Reports Coast and Geodetic Survey (C&GS), and the earlier series, C&GS Technical Bulletins.

Microfiche for the following reports is available from the National Technical Information Service (NTIS), U.S. Department of Commerce, Sills Bldg., 5285 Port Royal Road, Springfield VA 22161. (NTIS accession numbers given in parentheses.) Write to source for price.

CHEMICAL CONTAMINANTS
IN NORTHEAST UNITED STATES
MARINE SEDIMENTS

Paul Boehm
Energy Resources Co., Inc.
National Ocean Service, NOAA, Rockville, Md.

1. Abstract

The initial (1981) segment of the NEMP area-wide sediment sampling and organic contaminant analytical program was conducted covering the Chesapeake Bay to Gulf of Maine region. Replicate samples taken from 28 stations (Figure 1) in each of two seasons were analyzed for the gross sediment quality parameters of total organic carbon (TOC), sediment grain-size distributions (GSD), and total Kjeldahl nitrogen (TKN). Additionally, five replicate cores from eight stations (Figure 1) were analyzed for their polychlorinated biphenyl (PCB), polynuclear aromatic hydrocarbon (PAH) and coprostanol (a fecal steroid) content. Statistical analyses of the concentration data were used successfully to assess changes in compound levels at each station and to assess differences between stations. Diagnostic ratios of PCB/TOC, coprostanol/total steroids, and coprostanol/PCB were used to determine whether concentration differences were due to geochemical and sedimentological phenomena or were due to real additional pollutant inputs to a given site. An organic pollutant monitoring system has thus been set in place which will allow for statistically valid monitoring of pollutant inputs to the benthos as reflected in sediment organic geochemistry.

2. Objectives

The goal of this effort was to perform analytical measurements of the polychlorinated biphenyl (PCB), polynuclear aromatic hydrocarbon (PAH) and coprostanol contents of approximately 70 sediment cores and to additionally analyze approximately 400 sediment cores for their total organic carbon (TOC), total Kjeldahl nitrogen (TKN) and grain size distribution (GSD). Samples were taken as part of a northeastern U.S. area-wide study from Chesapeake to Massachusetts Bays with more intensive sampling taking place in the New York Bight region.

PCB and PAH distributions are particularly relevant in determining pollution inputs and impacts as these components are ubiquitous contaminants of estuarine and nearshore sediment (Sayler, et al. 1978; West and Hatcher, 1980; Boehm, 1980, 1982; Windsor and Hites, 1979). Additionally these component classes include both toxic and mutagenic compounds.

The presence of coprostanol, a fecal steroid, has been used as an indicator of municipal sewage contamination (Hatcher and McGillivray, 1979; Hatcher, et al., 1977; Escalana, et al., 1980; Kanazawa and Teshima, 1978; Boehm, 1980, 1982).

The detailed organic chemical makeup of sediments along with important support measurements of TOC, TKN and GS define geochemical pollutant sources in the northeast region and can be used to measure changes in the nature and quantity of pollutant inputs with time. TOC varies inversely with grain size while the ratio of TOC to TKN has been used to indicate the type of organic material(s) present. Grain size is an extremely important determinant in defining the habitat for

benthic organisms. The ratio of the abundance of certain organic chemicals (e.g., PAH, PCB) to TOC can also be used to define regional "geochemical provinces" (Boehm, 1981a), and to thus monitor changes in a particular province.

3. Summarization of Activities and Rationale

3.1 Sampling Activities

For the first phase of this program one hundred and thirty-three (133) sediment cores (0-10 cm) from 27 stations were taken for sediment grain size, TOC and TKN measurements. These consisted of five replicate cores at eighteen stations occupied during cruise AL81-07 (area wide survey) and five replicate cores at eight stations and three replicates at one station occupied during cruise AL81-09 (New York Bight survey). Additionally, five replicate cores taken at 8 stations located outside Chesapeake Bay, at the Philadelphia dumpsite, on the southern flank of Georges Bank, in Buzzards Bay, in Massachusetts Bay, in the "mud patch" south of Nantucket Island, and at two stations in the New York Bight region (equals 40 samples) were obtained for PCB, PAH and coprostanol analyses. The second phase of the program involved the analyses of one hundred and forty (140) sediment cores from 28 stations for grain size, TOC and TKN parameters. These cores were taken on NEMP cruise A1-82-01 in February of 1981. Ten (10) cores from two stations just seaward of the mouth of Delaware Bay taken in November 1981 were subjected to these analyses as well. Additionally ten (10) cores from the 106 Mile Deepwater Dumpsite location were analyzed. Five replicate cores from the same eight (8) stations as described above were analyzed for PCB, PAH, and coprostanol.

All samples were obtained by NOAA/NMFS personnel using a Pamatmat multiple quartz corer. Details of the sampling locations are presented in Figure 3-1 and can be found in Reid et al., 1981.

3.2 Analytical Methodology

The analytical methodologies used in this program are summarized in Table 3-1 and the detailed methods for organic chemical measurements shown in Figures 3-2 and 3-3.

4. Summarization of Findings

4.1 Sediment Character, Gross Chemistry

This section presents the absolute levels of TOC, TKN and GSD data on percent silt/clay (greater than 4 phi). Detailed TOC, TKN and GSD data are presented in Tables A-1 to A-33 in the Appendices in Section 8. The data from the five replicates from each station are given as the mean plus or minus one standard deviation, in Tables 4-1 and 4-2.

TOC and TKN values currently reported (1981 and 1982) are compared (Table 4-3) with values previously obtained from two 1980 samplings. Comparisons are generally quite good. Discrepancies most notably occur at Station 35, 16C and 17 where sampling variability is suspected. In addition, there is some problem with the location of Station 17, with different maps showing differing locations (Reid et al., 1981; White, 1981).

The ratio of organic carbon to kjeldahl nitrogen (TOC/TKN) has in the past been computed to aid in the interpretation of

TABLE 3-1
SUMMARY OF ANALYTICAL METHODS

PARAMETER	METHOD	REFERENCE	DETECTION LIMIT
Grain Size (GSD)	Sieve and pipette analysis	Folk (1974)	NAA ^a
Total Kjeldahl Nitrogen (TKN)	Acid digestion - automated colorimetry	USGS (1979); Technicon (1976)	10 µ/g dry wt.
Total Organic Carbon (TOC)	High temperature combustion	Gibbs (1977)	0.01 mg/g dry wt.
PCB	Gas chromatography (GC); electron capture detection	Albro & Parker (1980); Boehm (1980a)	0.1 ng/g dry wt.
Coprostanol	Capillary GC - flame ionization after derivatization	Hatcher & McGillivray (1979); Boehm (1980a)	0.005 µg/g dry wt.
PNAH	Capillary GC - flame ionization after Sephadex cleanup	Ramos & Prohaska (1981); Brown et al. (1980); Boehm et al. (1981) Boehm (1980a)	1 ng/g dry wt. (individual component)

^aNot Applicable.

variable TOC and/or TKN concentrations in sediment (Freeland and Swift 1978; Milliman 1972) and to reveal possible sources of observed variability. This ratio is generally greater than 10 in coastal areas where riverine and/or anthropogenic influences are important, and 5-10 where marine organic matter (i.e., plankton, etc.) influences the sediment composition. While there is some variability in this ratio at a given station over time (Table 4-3) there is an obvious relationship between this ratio and the depositional environment at a given station. TOC/TKN values tend to be greater than 9 in areas of higher deposition (of terrigenous silt/clay, and associated pollutants) as evidenced by silt/clay percentages (Tables 4-1 and 4-2) of greater than ~1%. Thus stations 15A, 16A, 16B, 16C, and 33 in the New York Bight, 28 and 35 in Massachusetts Bay/Gulf of Maine, 18 in Long Island Sound, and 20 in the shelf deposition region off Rhode Island all exhibit high TOC/TKN ratios. Note that where grain size was found to be the same in 1981 and 1982 TOC/TKN ratios were similar, but where the sediment character was found to differ (e.g., stations 24, 31) the ratio changed. There are, however, exceptions to these "rules" (e.g., stations 17, 36). Although TOC/TKN values are generally in the range of 5-30 and perhaps can be grouped, the ratio is insensitive as a monitoring parameter both due to the variability of the ratio and its insensitivity to trace level additions of pollutants and even to large (100 ppm or so) additions of, for example, petroleum. A 100 ppm addition of oil (mostly carbon and hydrogen) to a sediment whose TOC was 5 mg/g (0.5%) and TKN was 400 mg/g would show a TOC change upwards to 5.1 mg/g (well within the range of natural variability at a given station) and a TOC/TKN change from 12.5 to 12.75.

TOC and TKN are best utilized as normalization parameters for trace level organics or metals (see section 4.2, 4.3) or as measurements which help select samples for additional (PCB, PNAH, coprostanol) analyses.

4.2 Polychlorinated Biphenyls

PCB concentrations in these nearshore and offshore sediments ranged from a high of 290 ± 110 ppb at Station 16B in the Christiaensen Basin of the New York Bight Apex in 1982 to $0.16 \pm .13$ ppb at station 22 (NEMP) in the shelf region of Georges Bank (Table 4-4, Figure 4.1). PCB concentrations at the center of Buzzards Bay (station 36) were variable (12.8 ± 7.7 ppb when sampled in 1981, and 44 ± 7.4 ppb in 1982), but were similar during the two samplings at station 37 within the depositional "mud patch" south of Nantucket and within the inshore Hudson Canyon (station 33) (i.e., 8-9 ppb). There was sizeable variation in the "mud patch" (station 37) values in 1981 (0.6-30 ppb) and at other stations. The median values and mean values are presented in Table 4-4. In most cases means and median values were similar. Coefficients of variation (s/x) indicated within station variabilities of 17 to 150% (most often 50-70%) thus indicating the need for multiple sampling at each station. Analytical variability (3 sub-samples of a particular sample) ranged from 4-20%.

PCB values can be put into perspective when viewed versus other recent coastal sediment data (Table 4-5 and 4-6). We see that the absolute PCB levels for the New York Bight/Hudson Canyon samples (stations 16B and 33), .006-.29 ppm, and the other samples fall within expected ranges.

Statistical comparisons (Table 4-7) were made to compare PCB data from the two samplings. Note that PCB values are statistically higher at stations 9, 36, 16B during the second sampling. As the PCB/TOC ratios (see next paragraph) are also higher one concludes that the 1982 samples contained a greater proportion of PCB relative to TOC thus implying a definitive increase in PCB levels. However, our knowledge of the three

sites, New York Bight, Philadelphia Dumpsite, and Buzzards Bay suggests that inherent patchiness at these sites (i.e., sampling variability) may contribute to this increase at Philadelphia dumpsite rather than new PCB inputs, and that there are equal probabilities of new inputs and sampling variability accounting for observed increases at stations 16B and 36. PCB values at each station were also compared to those of the other stations within each of the two (1981, 1982) sample sets (Table 4-8).

Since the program involved analysis from only eight stations over a wide geographic area, no uniform geochemical relationships can be assumed to govern pollutant distributions in sediment. However, if one looks at the relationship of PCB to TOC (Table 4-9) we find that the "unpolluted" coastal sediments from stations 3, 9, and 22 have low (0.14×10^{-6} to 0.29×10^{-6}) PCB to TOC ratios in 1981. At the more PCB-impacted stations, a greater proportion of the TOC is PCB material. Thus, PCB/TOC ratios at stations 36 and 37 are similar to each other in 1981 while they are much higher both in the 1981 and 1982 New York Bight sample sets (6.1 and 11.4×10^{-6}). Furthermore, PCB/TOC increased at the Buzzards Bay station (36) in 1982 (6.1×10^{-6}). Thus PCB/TOC is sensitive to variations in absolute PCB inputs, and is an indicator of PCB hot-spots not attributable merely to a grain size phenomenon (i.e., TOC input). For example it is quite possible to see an increase or a decrease in PCB levels with no change in the PCB/TOC ratio.

Stations 16B and 33 have been sampled previously as part of the New York Bight Benthic survey (Boehm 1980). At that time PCB values were determined to be 55 and <0.5 ppb respectively. The values reported here are notably higher, indicative of the inherent patchiness in the system or increased levels due to PCB inputs.

^aSum of five steroids: coprostanol, cholesterol, cholestanol, stigmasterol, β -sitosterol.

4.3 Coprostanol

The amounts of fecal steroid, coprostanol, in the surface sediments (Table 4-10, Figure 4.2) ranged, on the average, from 0.01 to 26.7 ppm. Only in the New York Bight station within the sewage depositional area (16B) is the coprostanol value, 17.4 ppm (1981) and 26.7 ppm (1982), reflective of gross sewage contamination. These values are similar to that determined previously for this station, 11 ppm (Boehm 1980). Similarly, the station 33 values for the three data sets are similar (1980 : .07; 1981 = .05; 1982 = .08 ppm). At all other stations other than station 36 (Buzzards Bay) in 1982, coprostanol values of 0.01 to .035 ppm are "typical" of shelf values (nd - 0.06; Boehm 1980) determined for New Jersey and Long Island Atlantic shelf values.

Statistical comparisons are presented in Tables 4-11 and 4-12 for seasonal and spatial comparisons respectively. Coprostanol values remain the same at stations 9, 35, 37, and 33 while they differ at stations 36, 16B (increase in 1982) and 3, 22 (decrease in 1982).

The importance of sewage-derived organic matter relative to non-sewage steroidal inputs can be examined using the ratio of coprostanol to total measured steroids (Table 4-9). It can be seen that only at station 16B within the New York bight and perhaps at station 36 within the Buzzards Bay are sewage-related inputs to sediments evidenced by virtue of coprostanol to total steroid ratios in the 0.05 to 0.6 range. A scale of 0 to 0.74 has previously been established (Boehm 1980) to indicate the relative importance of sewage-related compounds to marine sediments. Thus it can be seen that sewage-associated pollutants are low-level ubiquitous components of offshore marine sediments.

4.4 Relation of PCB to Coprostanol

Another potentially useful parameter is that of the ratio of coprostanol to PCB. Although PCB are abundant in sewage sludges, PCB inputs are of course not limited to sewage-related sources. Coprostanol to PCB ratios near the sewage dumpsite in the New York Bight have been determined to be 150-200 (Boehm 1980). A value found in sediments within this range can therefore be interpreted as meaning that most PCB found in the sediments are sewage related. Theoretically this ratio approaches zero as "pure" PCB inputs (sewage-free) are approached. Interestingly, consistently elevated ratios are observed (Table 4-9) for station 16B, due to its location adjacent to the sewage dumpsite, but also for Station 3 off-shore Chesapeake Bay, and for the Georges Bank station (22) indicating that PCB inputs to sediments from these stations have a significant sewage-related source. Some of the PCB observed at the other stations (9, 35, 37, and 33) show a small but significant sewage influence (copros/PCB = 5-20). Most interestingly, and quite indicative of the power of this ratio as a diagnostic geochemical tool is the fact that at station 36 the ratio is low (3-4) while the PCB levels are high. This implies a non-sewage source for PCB which we know in Buzzards Bay to be related largely to industrial rather than sewage-mediated inputs. The trends in the coprostanol/PCB ratio can be statistically evaluated (Tables 4-13 and 4-14) for seasonal and spatial trends. Note that increases in PCB levels without concomitant coprostanol increases occur at stations 3, 9, and 33.

4.5 Polynuclear Aromatic Hydrocarbons (PAH)

PAH compounds are ubiquitous constituents of marine sediments from the continental shelves of the world's oceans

(Windsor and Hites, 1979). PAH were detected in nearly all sediments from the study area, the exception being station 9 near the Philadelphia dumpsite in 1981. The station 9 collection from 1982 did contain detectable levels primarily of fluoranthene and pyrene (Table 4-15). Concentrations range from 1.0 ppb at station 22 on Georges Bank to 31,000 ppb in New York Bight (Table 4-15, Figure 4.3). Interestingly the "mud patch" depositional site (37) contained moderate PAH levels (100-150 ppb) indicating that this represents a true pollutant depositional area. Massachusetts Bay (35) contained roughly a part per million of total PAH (.650-1.22 ppm).

Trends in PAH data are quite dissimilar from those of PCB indicating that transport routes and sources for these two pollutant classes differ. For example, while PCB levels were seen to increase between 1981 and 1982 at station 16B, the PAH levels decreased. While PAH increased at stations 35 and 22, the PCB levels remained the same at 35 and decreased at 22. However, PAH (and PCB) levels remained the same at stations 3, 33, and 37.

Sources of PAH compounds to the sediments are generally discerned from the following criteria: Petroleum sources are indicated by a high amount of alkylated (C_1 , C_2 , C_3 , C_4) naphthalenes, phenanthrenes, fluorenes, and dibenzothiophenes relative to the parent (unsubstituted) compounds (i.e., C_0) (Youngblood and Blumer, 1975); combustion sources are indicated by an equal or larger amount of C_0 compounds relative to C_1 and C_2 plus large relative quantities of the larger PAH compounds (fluoranthene and pyrene [4 rings], benzofluoranthene and the benzozyrenes [5 rings]). The percentage of total PAH attributable to petroleum can be approximated according to Table 4-16. PAH sources to all but the heavily impacted New York Bight station (16B) are primarily 90-95% of a

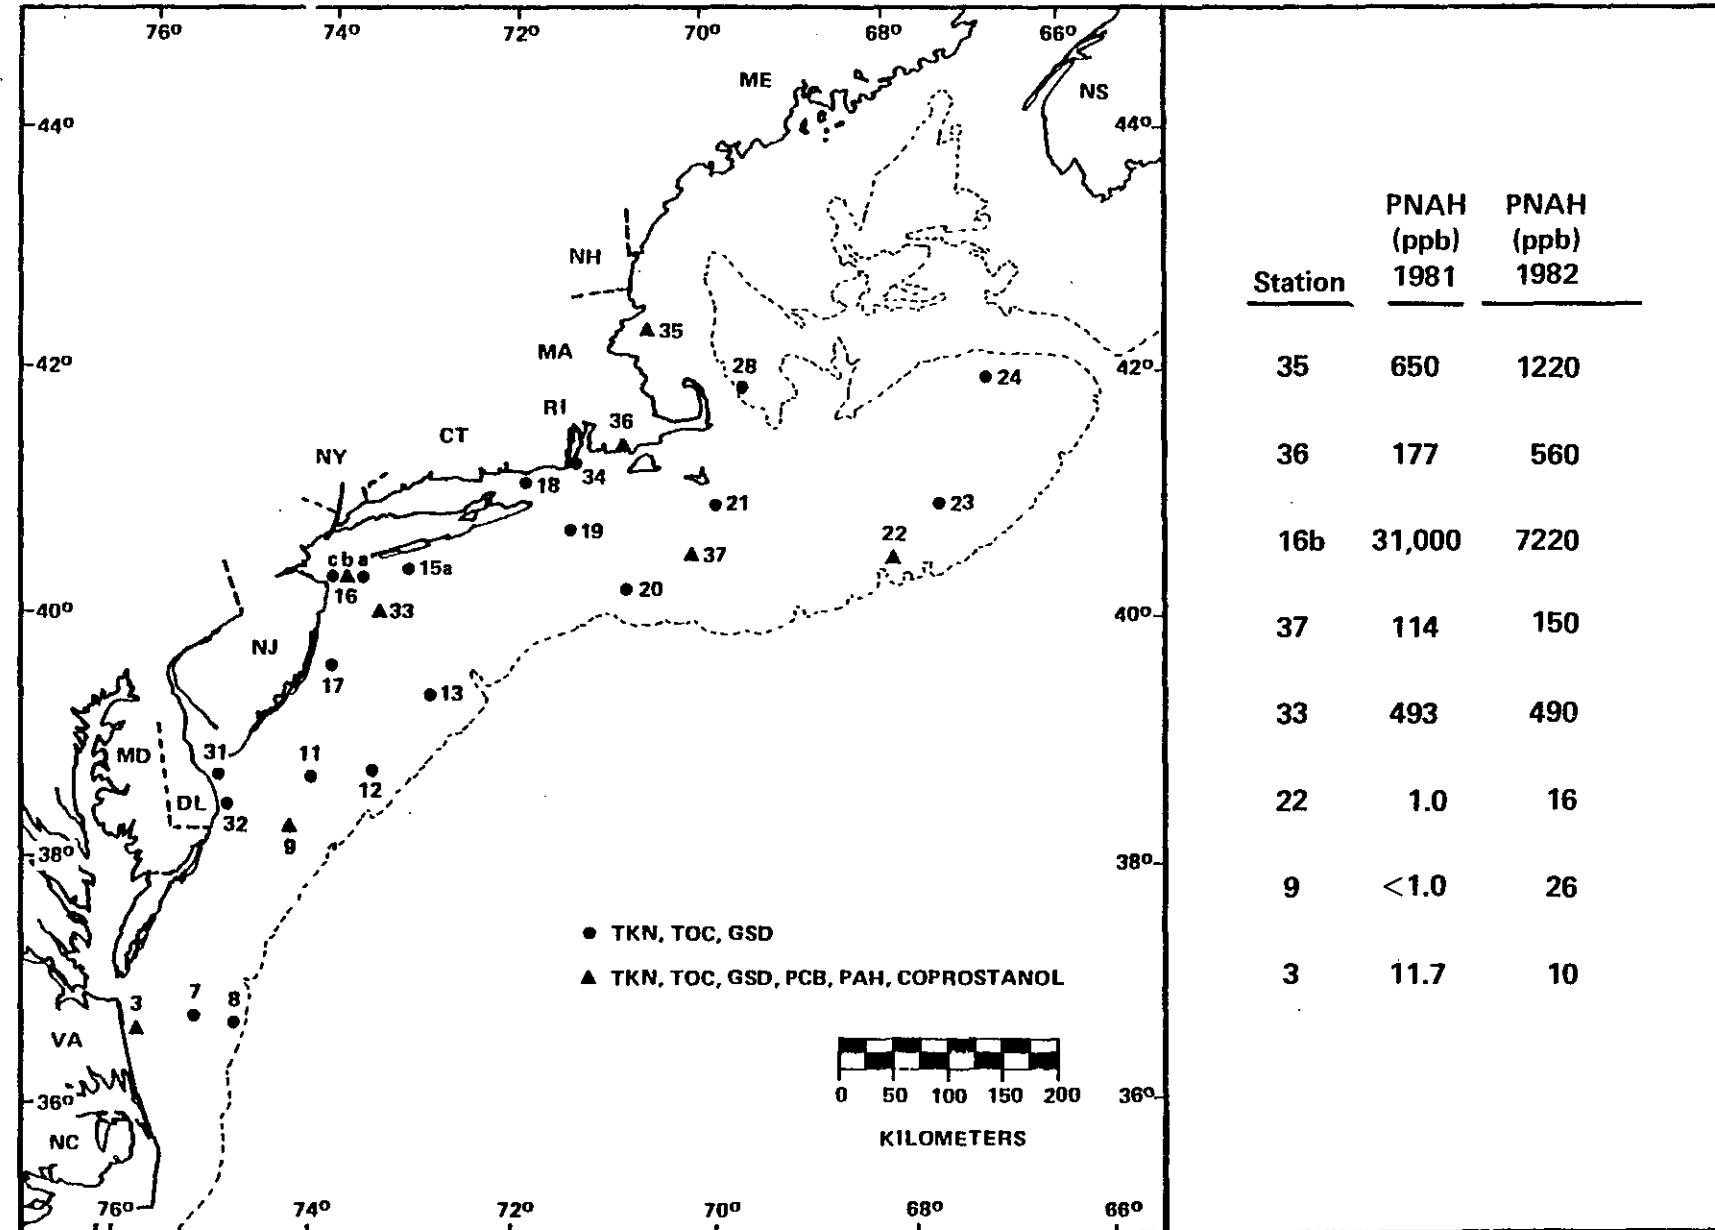

Figure 4-3. PNAH concentrations in sediments.

combustion origin with 3-5 ring aromatics dominant. PAH sources to station 16B are a mixture of petroleum (35-50%) and combustion-derived material. Note that when one compares 1980 and 1981 determined PAH concentrations (Table 4-15) the increase at Station 16B is primarily in the naphthalene and dibenzothiophene compound series, indicating a petroleum-related increase. However, in spite of quantitative differences at some of the stations (e.g., 9, 22, 35, 16B) the contributions of the main source classes (Table 4-16) remain relatively constant.

What significance do the PAH values have? In general as aromatic compounds get larger by either increased ring size or methyl substitution up through the alkyl-phenanthrenes and fluoranthene, they become more toxic. Beyond this molecular size the molecules become less soluble in water and hence less readily available in the sense of resulting in acute toxicity. However, many of the five-ringed compounds are carcinogenic (see Table 4-17) once introduced to the animal via uptake routes other than through the water soluble fraction (i.e., sediment uptake, or uptake of contaminated food). Thus the PAH compounds are both acute toxicants and carcinogens depending on molecular size.

5. Summary of Interpretation of Findings

The PCB, coprostanol, and PAH data sets along with the TOC measurements represent a highly useful set of geochemical data with which to assess pollutant inputs to marine sediments. Although the stations are widely separated several important trends are noted in the data.

There appears to be a strong direct relationship between TOC and TKN levels which is revealed in the TOC/TKN ratio in

TABLE 4-16

Tables 4-1 through 4-3. Terrigenous organic matter tends to have high values (>10). TOC/TKN ratios decrease with distance from shore or from anthropogenic input reflecting inputs of marine TKN material. Thus it can be seen from the tables that there is a gradation in this ratio with high values (>10) indicative of terrigenous and anthropogenic inputs characteristic of the impacted stations of New York Bight, Massachusetts Bay, Buzzards Bay, and the depositional areas south of Nantucket and in the Gulf of Maine.

As increased TOC/TKN ratios are indicative of direct dumping or of silt/clay depositions, it is not surprising to find highest PCB, coprostanol and PAH levels at those stations with highest silt/clay content (33, 16B, 37, 36, 35). Of particular importance are the parameter ratios of coprostanol/total steroids, coprostanol/PCB, and PCB/TOC which indicate several important facts. The PCB at stations 35, 36, 37, and 16B are more abundant than if they were "normally" deposited by geochemical mechanisms, thus implying local inputs of contaminants. These observations are consistent with our knowledge of inputs of contaminants to urbanized regions (Stations 16B, 33, 36, 35) but are quite new for the offshore depositional areas (e.g., Station 37). Presumably other offshore depositional areas having high TOC or silt/clay contents (e.g., Stations 28, 20) would reflect these elevated PCB levels as well.

The source of PCB is nicely revealed in the coprostanol to PCB ratio (Table 4-10). At Station 3, although levels of PCB and coprostanol are low, this ratio (100-150) indicates that most of the PCB is sewage related. Similarly, elevated ratios at Stations 9 and 22 reveal low level sewage impacts, not obvious through single parameter (e.g., PCB alone) measurements. In contrast, elevated levels in Buzzards Bay (36) are shown not to be related to sewage but to industrial inputs.

Similar trends are revealed in the PAH data, with those sediments of higher silt/clay content higher in PAH. However, while most of the PAH material in the offshore samples and in the Massachusetts and Buzzards Bay samples is closely related to combustion sources (urban air fallout and runoff), the New York Bight samples are heavily laden with petroleum aromatics. If it is assumed that naphthalenes, dibenzothiophenes and one half of the total phenanthrenes less phenanthrene itself are from petroleum, while the other PAH constituents are combustion related, then about 40% of PAH in New York Bight (16B) sediments are from petroleum. This decreases to ~10% further offshore (33). In contrast, less than 10% of offshore PAH, and ~10% of PNAH in the bays are due to petroleum-type inputs. Note that in the 1980 survey only about 20% of the PAH at Station 16B was petroleum related. Trends in PCB and PAH data indicate that their distributions, although related to the fineness of the sediment, are decoupled, indicating differing sources for these two compound classes.

Statistical differences in PCB and coprostanol levels are noted for several of the stations (16B, 36) which may be attributable to increases in pollutant levels. The significant within-station variability suggests that the analysis of sample replicates is crucial in being able to compare pollutant changes with time.

Thus combinations of TOC, TKN, GSD, and organic parameter measurements provide powerful quantitative and compositional tools for monitoring pollutant histories and changes in offshore benthic environments.

6. Inventory of Data Acquired

Table 6-1 presents a list of those samples analyzed and the nature of the analyses performed on each sample. The location of the sampling stations is shown in Figure 3-1.

7. Statement of Problems

No significant problems have been encountered on this project.

8. Data Appendices

TOC and TKN data for individual replicates are presented in Table A-1. PCB and coprostanol replicate data are presented in Table A-2. GSD data for replicates at each station are found in Tables A-3 through A-34.

(Continued from inside front cover)

- NOS 70 NGS-5. Selenocentric geodetic reference system. Frederick J. Doyle, A. A. Elassal, and J. R. Lucas, February 1977 53 pp. (PB266046)
NOS 71 NGS-6. Application of digital filtering to satellite geodesy. C. C. Goad, May 1977 73 pp. (PB270192)
NOS 72 NGS-7. Systems for the determination of polar motion. Soren W. Henriksen, May 1977, 55 pp. (PB274698/AS)
NOS 73 NGS-8. Control leveling. Charles T. Whalen May 1978, 23 pp. (PB286838)
NOS 74 NGS-9. Survey of the McDonald Observatory radial line scheme by relative lateration techniques. William E. Carter and T. Vincenty June 1978, 33 pp. (PB287427)
NOS 75 NGS-10. An algorithm to compute the eigenvectors of a symmetric matrix. E. Schmid, August 1978, 5 pp. (PB287923)
NOS 76 NGS-11. The application of multiquadric equations and point mass anomaly models to crustal movement studies. Rolland L. Hardy, November 1978, 63 pp. (PB293544)
NOS 77 Numerical simulation of sedimentation and circulation in rectangular marina basins. David R. Askren, January 1979, 137 pp. (PB294107)
NOS 78 Wave sensors survey. Richard L. Ribe, July 1979, 48 pp. (PB80 118581)
NOS 79 NGS-12. Optimization of horizontal control networks by nonlinear programing. Dennis Milbert, August 1979 42 pp. (PB80 117948)
NOS 80 Circulation and hydrodynamics of the Lower Cape Fear River, North Carolina. Joseph M. Welch and Bruce B. Parker, August 1979, 117 pp. (PB80 117088)
NOS 81 Formulas for positioning at sea by circular, hyperbolic, and astronomic methods. James Collins, February 1980, 30 pp. (PB80 184757)
NOS 82 NGS-13. Feasibility Study of the Conjugate Gradient Method for Solving Large Sparse Equation Sets. Lothar Grundig, February 1980, 19 pp. (PB80 180235)
NOS 83 NGS-14. Tidal Corrections to Geodetic Quantities. P. Vanicek, February 1980, 30 pp. (PB80 189376)
NOS 84 NGS-15. Application of Special Variance Estimators to Geodesy. John D. Bossler, February 1980, 8 pp. (PB80 223332)
NOS 85 NGS-16. The Bruns Transformation and a Dual Setup of Geodetic Observational Equations. Erik W. Grafarend, April 1980, 71 pp. (PB80 202302)
NOS 86 NGS-17. On the Weight Estimation in Leveling. P. Vanicek and Erik W. Grafarend, May 1980, 34 pp. (PB81 108284)
NOS 87 NGS-18. Crustal Movement Investigation at Tejon Ranch, Calif. Richard A. Snay and Michael W. Cline, June 1980, 31 pp. (PB81 119000)
NOS 88 NGS-19. Horizontal Control Surveys. Joseph F. Dracup, June 1980, 32 pp. (PB81 133050)
NOS 89 The Response of the Shelf to Hurricane Belle, August 1976. Richard C. Patchen and Bernard W. Gotthold, August 1981, 36 pp. (PB82 155953)
NOS 90 NGS-20. Precise Determination of the Disturbing Potential Using Alternative Boundary Values. Erwin Groten, August 1981, 70 pp. (PB82 150392)
NOS 91 NGS-21. Results of Photogrammetric Control Densification in Ada County, Idaho. James R. Lucas, December 1981, 74 pp.
NOS 92 NGS-22. Results of Leveling Refraction Tests by the National Geodetic Survey. Charles T. Whalen, November 1981, 20 pp. (PB82 193921)
NOS 93 Is the East River, New York, a River or Long Island an Island? R. Lawrence Swanson, Charles A. Parker, Michael C Meyer, and Michael A. Champ, June 1982, 23 pp. (PB82 252404)
NOS 94 NGS-23. Scribing, Graduation, and Calibration of U.S. Coast and Geodetic Survey Leveling Rods During 1877-1968. William E. Strange, August 1982, 33 pp.
NOS 95 NGS-24. Proceedings of Symposium No. 5: Geodetic Applications of Radio Interferometry (IAG). William E. Carter, Convenor and A. Tusuchiya, Co-convenor, 1982, 346 pp
NOS 96 NGS 25. Allocation of Inertial Surveying System Model Parameters. Charles W. Challstrom, November 1982, 101 pp.
NOS 97 NGS 26. An Inertial Survey Adjustment Program: Implementation and Validation. Dennis G. Milbert, November 1982, 91 pp.
NOS 98 NGS 27. Preliminary Data Analysis of Inertial Survey System Test in Southwest Arizona. George Leigh, in press.

NOAA SCIENTIFIC AND TECHNICAL PUBLICATIONS

The National Oceanic and Atmospheric Administration was established as part of the Department of Commerce on October 3, 1970. The mission responsibilities of NOAA are to assess the socioeconomic impact of natural and technological changes in the environment and to monitor and predict the state of the solid Earth, the oceans and their living resources, the atmosphere, and the space environment of the Earth.

The major components of NOAA regularly produce various types of scientific and technical information in the following kinds of publications:

PROFESSIONAL PAPERS—Important definitive research results, major techniques, and special investigations.

CONTRACT AND GRANT REPORTS—Reports prepared by contractors or grantees under NOAA sponsorship.

ATLAS—Presentation of analyzed data generally in the form of maps showing distribution of rainfall, chemical and physical conditions of oceans and atmosphere, distribution of fishes and marine mammals, ionospheric conditions, etc.

TECHNICAL SERVICE PUBLICATIONS—Reports containing data, observations, instructions, etc. A partial listing includes data serials; prediction and outlook periodicals; technical manuals, training papers, planning reports, and information serials; and miscellaneous technical publications.

TECHNICAL REPORTS—Journal quality with extensive details, mathematical developments, or data listings.

TECHNICAL MEMORANDUMS—Reports of preliminary, partial, or negative research or technology results, interim instructions, and the like.

Information on availability of NOAA publications can be obtained from:
